ABSTRACT

PURPOSE: The aim of this study was to evaluate the rhombic three-dimensional plate in fixation of displaced low subcondylar mandibular fractures clinically and radiographically.

MATERIALS AND METHODS: This is a prospective, interventional, single armed case series study that was carried out on twelve patients with displaced low subcondylar mandibular fracture. Open reduction and internal fixation was utilized to treat those fractures using rhombic 3D plate, patients were collected from the department of Oral and Maxillofacial surgery, Faculty of Dentistry, Tanta University. All cases were treated with retromandibular approach. Post-operative evaluation: all patients underwent regular follow up for six months. The following parameters were evaluated: a. Maximal mouth opening, b. Lateral and protrusive mandibular movements, c. Chewing and occlusion, d. Clicking and tenderness of TMJ, e. Vertical height of the ramus, f. Anteroposterior angulation of the condyle.

RESULTS: 6 months after the operation, the functional parameters returned to normal, with an average mouth opening of 43.6 mm, protrusion of 9.6 mm, and laterotrusion of 10.5 mm. No clicks or tender TMJ, normal function of facial nerve. Radiographic controls showed good fracture alignment, no plate fracture, bending or loose screws were observed.

CONCLUSIONS: The clinical and radiographical data suggested that the rhombic three-dimensional plate is suitable for treatment of condylar fractures and provided stable fixation.

Key Words: Low displaced condyle fractures - mandibular trauma rhombic 3d plate.

INTRODUCTION

Mandibular fractures are the third most frequent maxillo-facial fractures after those of the nasal and zygomatic bones. Mandibular condylar neck fractures and subcondylar fractures constitute 19 - 29% and 62 - 70% of all mandibular fractures respectively.¹ ²

Condylar fractures deserve a special consideration apart from rest of the mandible due to their anatomical differences and healing potential. However, the sequelae of the condylar injuries cannot be considered suboptimal with regard to malocclusion, reduced mouth opening, deviation of the mandible, impaired mastication, ankylosis and internal derangement.³ ⁴

For decades, closed treatment has been preferred because it is easier and less invasive, and the results are comparable with no surgical complications. On the other hand it may employ varying periods of intermaxillary fixation (4 to 6 weeks) followed by aggressive physiotherapy. In addition, long-term complications like pain, arthritis, malocclusion, deviation of the mandible on opening and closing movements, temporomandibular joint dysfunction, facial asymmetry and ankylosis.⁵ ⁷

The debate regarding the optimal treatment of these fractures is still open and the decision concerning appropriate intervention for every fractured condyle
The following criteria: 1- Medically fit patients free from ethically cleared by the research ethical committee. The study was conducted at the Department of Oral and Maxillofacial Surgery, Faculty of Dentistry, Tanta University. All patients signed an informed consent before undergoing the surgery. The study was ethically cleared by the research ethical committee.

To qualify for surgery, patients were required to fulfill the following criteria: 1- Medically fit patients free from relevant conditions contraindicating surgery. 2- Patients aged above 16 years old. 3- Patients suffering from displaced low subcondylar mandibular fracture indicated for open reduction. Patients with relevant bone diseases or infected fracture site were excluded from the study.

Materials:

In this study, the plate which used for fixation of subcondylar mandibular fracture was the 3-dimensional rhombic plate (KLS Martin, Tuttlingen, Germany), which is manufactured of pure titanium (grade 2) of 1.0 mm thickness and secured with 5 screws of 2.0 mm head diameter. Also the plate has a unique feature of two gliding holes.

Methods:

A) Pre-operative Phase:

For all cases thorough history taking, clinical and radiographic examination were performed. All patients were subjected to full clinical examination by inspection and palpation of the fracture sites both extra- and intra-orally to detect the presence of edema, ecchymosis, soft tissue laceration, hemorrhage, site of fracture, dentition, derangement of occlusion, areas of tenderness, step deformities, mobility of fractured segments.

Radiographic examination was accomplished for all patients at the time of presentation. Digital panoramic, axial, coronal, 3D reconstruction computerized tomography (CT) were taken for all patients.

B) Operative Phase:

The surgery was carried out under general anesthesia with nasal intubation. Intermaxillary fixation (IMF) was done to provide proper occlusion before plate fixation. In order to expose the fracture, a retromandibular approach was made. The incision was made 2 cm posterior to the posterior border of the ramos of the mandible and 0.5 cm below the ear lobe. After incision, the parotid gland was separated from the sternocleidomastoid muscle and retracted superiorly. Sub periosteal dissection with stripping the masseter muscle off of the ramus was then performed to expose the fracture site. After the localization of the fracture, the proximal fragment is reduced to the correct anatomical position and fixed using rhombic 3D plate. The holes were than drilled and the plate fixed in place using 5 screws with 2 mm head diameter and 7 mm in length. After checking the correct reduction of the fracture and the stability of the internal fixation, the IMF was removed and the wound was closed in layers using polyglycolic polylactic 3- suture material (Vicryl, Ethicon, Cornelia, GA, USA) for deep layers and 40- polypropylene suture material (Prolene, Ethicon, Cornelia, GA, USA) for skin layer (Pterygo- masseteric sling, platysma, subcutaneous tissue and skin).
C) Postoperative Phase:

Antibiotic schedule was prescribed post-operatively for 5 days, Amoxicillin/Clavulanate potasium 1 gm IV twice daily, (Augmentin, GlaxoSmithKline, Brentford, London). In addition to anti-inflammatory drug, Diclofenac sodium 75 mg IV (Cataflam, Novartis, Basel, Switzerland). All patients were advised to stick to postoperative care instructions to prevent postoperative complications. Dressing change was done by nursing staff on daily bases. Sutures were removed after 5 to 7 days.

D) Follow-up Phase:

Clinical follow-ups were carried out in all patients after 1 week, 2 weeks, 3 weeks, 1 month, 3 months and 6 months. The follow-ups comprised an analysis of the occlusion, chewing according to ulgesic et al.16 questionnaire, the movement of the mandible in all three planes, joint function according to helkimo17 index, surgical wound for any signs of infection and any signs of facial nerve injury.

Radiographic studies were carried out using digital panorama, computed tomography (CT) immediately postoperative to check proper reduction and 1 month, 3 and 6 months to detect any cases of non-union, plate fracture, loosening of plate and screws. Vertical height of the ramus and antero-posterior angulation of the condyle was measured using digital panorama as proposed by Silvennoinen et al.18 during all follow up period. Readings were taken each time and then the average was calculated.

Statistical Analysis:

Statistical analysis was done using SPSS program (SPSS Inc. Released 2008. SPSS Statistics for Windows, Version 17.0. Chicago: SPSS Inc.) P value was calculated and data was collected & tabulated.

RESULTS

Clinical evaluation

This study included twelve patients with ages ranging from 18 to 55 years with an average of 29 years. The male to female ratio of the total of patients' material was 5:1 (10 men (83.3%) and 2 women (16.7%)).

All patients were presented with unilateral displaced low subcondylar fractures. 8 patients were presented with right subcondylar fractures and 4 patients showed left subcondylar fractures. In 11 patients the subcondylar fracture was associated with other mandibular fractures and only one patient had an isolated subcondylar fracture. Regarding the intraoperative experience, the application of the rhombic 3D plate was easier and required minimal manipulation to the soft tissue. None of the patients had non-union, plate fracture, loosening of plate and screws, infection of the surgical wound or facial nerve injury within the follow up period and all patients had satisfactory occlusion, normal chewing throughout the study period.

In all the 12 patients, the maximum mouth opening was between 38 to 48mm with average 43.67 mm. (Table 1). The protrusion was between 6 mm and 11 mm with average, 9.33 mm. (Table 2, figure 1). The results of the lateral movement showed no significant differences between the contralateral and fractured sides, so that symmetry of the lateral movements was observed. The lateral movement was between 6 mm and 11 mm with average, 9.3 mm. (Table 3, figure 2).

Radiographical evaluation

There was a minor displacement of the fragment and decrease of the mandibular ramus height which reflect the effectiveness in terms of the stability of the fixation observed in our study. This means that the fixation of the plates along an ideal osteosynthesis line enables effective

resistance to the bone tension forces acting on the condylar process during mandibular movements. None of our cases presented with loosening of screws or breaking of the fixation plate. Also, there was no disturbance in the fracture healing process. The average postoperative shortening of the ascending ramus height was less than 1 mm as shown in (Table 6 - Figure 3). The average degree of postoperative displacement of the condyle was less than 10 mm as shown in (Table 7) (Figure 4 - 7).

**DISCUSSION**

The gender distribution in our study shows a clear predominance of males, with a ratio of male (83.3%) to female (16.7%) of 5:1; this is inconsistent with Bormann et al. 19. This ratio demonstrates the more susceptibility of males to trauma due to more physical activity.

The evaluation of the concomitant fractures in our study showed 8.3% of isolated condylar fracture and 91.7% with additional mandibular fractures. This ratio explains that the condylar fractures were the result of the exertion of force which is not fully absorbed in the area of its primary application and leads to extreme bending of the mandibular neck which is the weakest point in the mandible, Zachariades et al.1, Villarreal et al.26 described similar fracture distributions.

From our experience, early surgical intervention (not more than 5 days from accident) leads to better and effective results. However, more time between the accident and surgery is required in cases of associated injuries, instability of vital signs or traumatic swelling. Barker et al.21 performed the surgery with an average of 2.5 days after the accident, whereby about 60% were treated on the first day, while Landes and Lipphardt 22 classified the operation as urgent and scheduled it on the fifth day at the latest. Recent studies have shown no increase in complications with a delay of repair beyond 24 hours until 7 days.32, 33

In our sample, stabilization was performed with 3D rhombic condylar fracture plate. This type of osteosynthesis showed none of the plates fractured, none bent or loosened screws during all recall periods, this is due to its rhombus shape which provides internal stability, as well as more optimal leverage that counteract posterior or anterior loads onto the proximal fragment.

Sikora et al.25, in their clinical evaluation of Delta plates reported no plate breakage. The same result was obtained by Haim et al.26 in their research on the biomechanics of Delta plates by their application in 40 porcine mandibles, as well as by Lauer et al.27 in a 1-year-long observation of 16 patients with all in all 19 Delta plates.

The mean maximal interincisal opening postoperatively was 43.67 mm (range 38 to 48 mm with SD 2.74 mm). This value is consistent with the results of Landes et al. 28. In our sample, 11 patients (91.7%) showed unlimited mouth mobility while only one patient (8.3%) showed slight limited mouth opening (38 mm) because of severely displaced condylar fracture before treatment that leads to a luxation of the mandibular head out of the glenoid fossa, which is associated with joint damage, functional loss of the lateral pterygoid muscle and postoperative scarring occurred during healing of the surgical site. Close explanation was also reported by Palmieri et al., Yang et al.29, 30

The mean of lateral protrusive movement postoperatively was 10.54 mm to the fractured side and 10.57 mm to contralateral side in 11 patients (91.7%), which shows statistically non-significant difference. This finding is in consistent with the results of Trost et al.31 who reported that symmetry of the mandibular movement was achieved in 84.4% of the patients (31 / 35) with less than 2 mm of homolateral deviation remaining in 15.6%. Our study showed a little reduction in lateral movement and slight restricted anterior movement of less than 7 mm in only one case (8.3%), this is may be due to adhesions in the articular cavity, postoperative scarring in the capsular ligament system and disc dislocation. This is also reported by Hlawitschka et al.32

Regarding facial nerve injury, none of the patients in our study showed any signs of facial nerve injury throughout the follow up period. Our experience indicates that this procedure requires careful surgery with careful blunt dissection of the soft tissue layers including parotid capsule so that the nerve can be protected and retracted, and also avoid prolonged traction on the operated site. However, Sikora et al.25 in their study diagnosed 7% of the patients during the postoperative period with a partial paresis of the facial nerve; in each of these cases, the correct function of the facial nerve returned spontaneously 3 months after the surgery.

The Helkimo index in our study showed that 91.7% of patients have a low score of D0 (symptom-free), 1 patient (8.3%) had D1 (slight dysfunction). Eulert et al.33 found absence of dysfunction D0 in 67.5% of surgically operated patients (34 / 51). Also Schneider et al.34 pointed out that 70% of patients (17 / 25) were symptom-free.

Similar to the data reported by Ellis et al.35 and Vesnave et al.36 in our series the average reduction of the mandibular ramus length of less than 1 mm was calculated and the average degree of postoperative displacement of the condyle was less than 10 throughout the follow up period.

Although this still needs to be tested biomechanically, the radiographic results of this study suggests that the modification of the 3 sided triangular pattern in the delta plate to a 4 sided rhombus form in the rhombus plate together with the effect of compression provided by the gliding holes provides us with a plate with higher stability than the 2 miniplates.

**CONCLUSIONS**

In conclusion, the application of the three dimensional rhombic plate for the stable osteosynthesis of condylar fractures ensures fully satisfactory treatment results, both from the clinical and radiological points of view.
